# Fire Spread and Smoke Development in Buildings

\*

A.Prof. Miodrag Drakulić, Ph.D. M.E.

Façades in Fire Seminar

Zagreb, May 28 2014

## Fire development

- Basically, fire development in enclosed spaces like buildings is related with so-called **buoyant, turbulent diffusion flame**.
- Fire dynamic depends on both **oxygen transport** to flame reaction zone and **amount of fuel** (furniture, floor and ceiling materials, clothes, equipment...).
- Oxygen transport to flame reaction zone is caused by two phenomena:
  - a) diffusion (molecular level)
  - b) air flow convection (macro level)

## Fire development

### Goals of fire protection measures:

- **Pre-flashover** period (app.  $t < 500^{\circ}\text{C}$ ):
  - Safety of people (tenable conditions for evacuation → low temperature exposure, no smoke, no toxic gases)
- **Post-flashover** period (app.  $600^{\circ}\text{C} < t < 1200^{\circ}\text{C}$ ):
  - Fire protection of the building (stability, integrity, construction collapse prevention) and firemen protection (time limited!)

## Smoke generation and propagation

- Smoke generation depends on many influenced factors. In fuel-controlled fires (with sufficient oxygen transport) smoke production can be calculated related to the characteristic **PLUME MODEL**.
- There are basically 3 plume models:
 

a) axisymmetric plume	}	Pre-flashover phase	
b) balcony-spill plume		}	Post-flashover phase
c) window jet plume			
- **IMPORTANT:** For the same Heat Release rate (HRR) smoke generation (mass flow) is different for different plume models! Differences could be up to 50% for the same geometric characteristics of the enclosure!
